TIBIA VARA DUE TO FOCAL FIBROCARTILAGINOUS DYSPLASIA

THE NATURAL HISTORY

C. F. BRADISH, STUART J. M. DAVIES, M. MALONE

From The Hospital for Sick Children, Great Ormond Street and Queen Mary's Hospital for Children, Carshalton

We report five patients with tibia vara due to focal fibrocartilaginous dysplasia of the medial aspect of the proximal tibia. In three patients spontaneous correction occurred, while in one of the remaining two treated by operation, a valgus deformity and neurological complications resulted. Conservative management is therefore recommended.

In 1985 Bell et al. reported three patients with tibia vara in association with a characteristic radiological appearance of the medial aspect of the proximal tibia; two of their patients were treated by operation, while spontaneous resolution had occurred by the age of seven years in the third. From the histology specimens of the lesions in these three patients they derived a name for the condition: focal fibrocartilaginous dysplasia.

We report another five patients, two of whom were treated surgically and three in whom spontaneous resolution occurred. From these patients the aetiology may be postulated.

CASE REPORTS

Our five patients were all referred either to The Hospital for Sick Children, Great Ormond Street or to Queen Mary's Hospital for Children, Carshalton, between 1974 and 1985. The details of our patients and the three originally described by Bell et al. (1985) are summarised in Table I.

All the patients presented with unilateral tibial bowing (Figs 1 and 2). The age at presentation varied from nine to 28 months, and distribution of the condition by sex or side seemed random. Radiographs revealed a cortical defect in the metaphyseal region of the medial tibia with an area of surrounding sclerosis (Fig. 3), a characteristic appearance.

Two of our patients underwent corrective surgery and biopsy was performed on one of them. Sections showed a mass of fibrocartilaginous tissue merging with dense fibrous tissue at the margins. Near the centre, the cells lay in lacunae in a manner suggesting fibrocartilage, while peripherally the appearance was more suggestive of tendinous tissue. There were no giant cells and no evidence of osteoid tissue or bone within the lesion.

Radiograph of Case 1 at presentation, aged 15 months.

Fig. 3

Photomicrograph showing dense fibrous tissue. On the left, cells lie in lacunae in a manner resembling fibrocartilage. This merges with cellular collagenous tissue on the right which resembles tendon (H&E × 125).

Fig. 4

(Fig. 4). The histological appearance in this case, and in that of a third patient who underwent biopsy only, was identical with that described by Bell et al. (1985).

In three of our patients (Cases 2, 3 and 4) there was improvement by the age of three years without surgical correction.

**DISCUSSION**

An analysis of the details of our patients and those reported by Bell et al. (1985) allows us to suggest the probable natural history of this condition. In both series, the children’s parents had noted the deformity in the first 18 months, although presentation at hospital was later than this for three patients. Initial deterioration had sometimes been observed. In this context it is noteworthy that patients treated by operation presented younger and it was the initial deterioration which prompted operation.

Spontaneous improvement in the bowing and the radiological lesion was observed in four patients. In these
patients the resolution started at about the age of two years and almost complete correction had occurred in three patients by the age of four years. The only patient in whom follow-up has been sufficient to show total spontaneous correction is Case 8.

From these patients it is impossible to state the incidence of this condition as both The Hospital for Sick Children and Queen Mary’s Hospital for Children are tertiary referral centres; however, the fact that only five patients have been seen between 1974 and 1985 indicates its rarity.

We believe that resolution would have occurred in all the patients had they been given the opportunity. Operation is to be avoided as it is unnecessary and has attendant hazards, as illustrated by Case 5 who, after operation, had a valgus deformity (Fig. 7) as well as neurological problems.

This variety of tibia vara should be added to the list of skeletal deformities in children in which spontaneous correction can be anticipated (Walker 1972).

We would like to thank Mr J. A. Fissen and Mr Geoffrey Walker for permission to present their patients. In addition we thank the photographic departments at both the Hospital for Sick Children, Great Ormond Street and Queen Mary’s Hospital for Children for their assistance. Mr G. W. Anderson, FIMLS, assisted in the preparation of the photomicrograph, and Miss Susan Wadd kindly typed the manuscript.
