LIMB SALVAGE USING DISTRACTION OSTEOREGENESIS
A CLASSIFICATION OF THE TECHNIQUE

From Kanazawa University, Japan

We report the results of distraction osteogenesis (callotasis) for the reconstruction of extensive defects after the excision of skeletal tumours in the limbs. Bone transport was performed in ten patients (five osteosarcomas and five giant-cell tumours), shortening-distraction in three (two osteosarcomas and one Ewing’s sarcoma), and distraction osteogenesis combined with an intramedullary nail to reduce the time of external fixation in six (three osteosarcomas, two chondrosarcomas, and one malignant fibrous histiocytoma).

The mean length of the defects after excision of the lesion was 8.4 cm. The mean external fixation index was 39.5 days/cm for the group treated by bone transport, 34.1 days/cm for the shortening-distraction group, and 24.0 days/cm for the group treated by distraction and an intramedullary nail. Functional evaluation gave excellent results in 12 patients, good in five and fair in two. There were ten complications in 19 patients, all of which were successfully treated.

We also classified reconstruction using distraction osteogenesis into five types based on the location of the defects after resection of the tumour: type 1, diaphyseal; type 2, metaphyseal; type 3, epiphyseal; type 4, subarticular reconstruction; and type 5, arthrodesis.

Our results suggest that reconstruction using distraction osteogenesis provides bone which will develop sufficient biomechanical strength and durability. It is beneficial in patients with an expectation of long-term survival and in growing children.

Received 27 August 1996; Accepted after revision 29 October 1996

There has been a dramatic improvement in the survival rate of patients with sarcomas and in the successful salvage of limbs as a result of progress in chemotherapy, radiological evaluation, surgical technique and the technology of materials and implants. Complications, however, such as deep infection, fracture, bone resorption, and breakage of prostheses still occur.

The challenge to provide long-lasting survival and function of the limb after reconstruction is now being met with biological solutions using living bone.

The ideal reconstruction should have biological affinity, resistance to infection, sufficient biomechanical strength, and durability. Vascularised bone transfer has limitations in length and strength and since 1990 we have been using distraction osteogenesis (callotaxis) which can regenerate bone of sufficient strength for reconstruction.

We now report our findings.

PATIENTS AND METHODS

Our series included 19 patients with tumours of a limb: ten had an osteosarcoma (seven conventional, two central low-grade, and one parosteal), five had a giant-cell tumour, two a chondrosarcoma, one a Ewing’s sarcoma, and one a malignant fibrous histiocytoma. Six patients with high-grade osteosarcomas treated with intra-arterial chemotherapy combined with caffeine had marginal excisions to preserve important structures such as the epiphysis, neurovascular bundles, and ligaments. Those with other malignant tumours underwent wide excision. Patients with giant-cell tumours had an en-bloc excision, thorough curettage at the subarticular area, and phenol cauterisation.

Distraction osteogenesis involved three different procedures: bone transport, shortening-distraction, or both combined with the use of an intramedullary nail. Two patients treated earlier by an autoclaved bone graft and one by a vascularised fibular graft had distraction osteogenesis after the failure of the primary operation.

Group I. Ten patients, five with osteosarcoma and five with giant-cell tumour, with a mean age of 26.4 years had bone transport. A monofocal ostectomy was performed to allow a bone segment to be transported to fill the defect produced by tumour resection. Bone graft was taken from the iliac crest and placed at the docking site to facilitate union soon
Distraction osteogenesis at the remaining epiphysis when this was followed by distraction. The three tumours were in the proximal femur, the distal femur, and the proximal tibia. The mean age of the patients was 14.3 years and the mean length of the defects was 8.2 cm (5.5 to 13). Two patients had chemotherapy during distraction. Two children, one with an osteosarcoma and the other with Ewing’s sarcoma, had the affected bone lengthened by an excess of 2 cm to correct anticipated discrepancy in leg length.

Group 3. This group was treated by bone transport or by shortening-distraction combined with an intramedullary nail to reduce the duration of external fixation (Fig. 1). Two techniques were used. When possible, distraction osteogenesis was performed after an intramedullary nail had been introduced with either proximal or distal locking screws. Screws were placed on the unlocked side after distraction was complete. If the remaining epiphysis was too thin to use an intramedullary nail or when part of the epiphysis was resected with the tumour, intramedullary nailing was performed after bone transport or shortening-distraction had been completed. After removal of the external fixator and placement of the second set of locking screws, a cast or splint was applied until the regenerated callus had consolidated. This group included three patients with osteosarcoma, two with chondrosarcoma and one with malignant fibrous histiocytoma. Their mean age was 41.3 years and the mean length of the defects was 7.9 cm (3.5 to 15). Two patients with osteosarcoma had chemotherapy during distraction. Two patients with pelvic chondrosarcoma had resection of the hip with an arthrodesis and a standard tibial lengthening with an intramedullary nail was performed for inequality of leg length.

Distraction was begun approximately 7 to 14 days after the operation at 0.5 mm twice daily or 0.25 mm four times daily. This was later either reduced to zero when the callus formation was delayed or impaired or increased to 1.5 mm per day when the callus formation was likely to consolidate prematurely. The external fixator was removed when sufficient consolidation had been obtained and a cast or splint applied for approximately four weeks. When callus formation was poor, distraction was delayed or compression and distraction of a moving segment (the accordion manoeuvre) was applied.

Evaluation. Three indices were used to evaluate the results: an external fixation index obtained by dividing the entire duration of external fixation by the length of bone regeneration; a distraction index obtained by dividing the duration of distraction by the length of bone regeneration; and a maturation index calculated by dividing the duration of external fixation, measured from the completion of distraction to the removal of external fixation, by the length of bone regeneration. The function of the affected limb was assessed according to Enneking. The mean period of follow-up for the 19 patients was 37 months (13 to 68). All patients were followed up for more than two years except for two who died after 13 months.

RESULTS

In the bone-transport group, an Ilizarov external fixator was used in nine patients and a unilateral lengthener in one. The mean external fixation index was 39.5 days/cm (27.9 to 63.5), the distraction index 19.5 days/cm (8.5 to 33.8) and the maturation index 18.8 days/cm (1.5 to 44.4). Seven complications occurred in six patients, including two skin invaginations, two pes equinus, one premature consolidation, one fracture at the docking site, and one subluxation of the head of the fibula. Skin invagination was treated by resection of elongated skin and suture. Pes equinus was managed by physiotherapy after removal of the Ilizarov apparatus. The apparatus was reapplied around the fracture at the docking site and the subluxation of the head of the fibula was reduced and fixed by screws during final removal of the Ilizarov fixator. The case of premature consolidation of regenerated bone was managed by a further percutaneous osteotomy, resulting in excellent bone regeneration. The function of the affected leg was rated excellent in eight patients, good in one and fair in one.

In the shortening-distraction group, an Ilizarov apparatus was used in all three patients. The mean external fixation index was 34.1 days/cm (32.7 to 34.8), the distraction index 9.4 days/cm (7.3 to 10.8) and the maturation index 23.4 days/cm (20.3 to 26.6). One patient with proximal tibial osteosarcoma had shortening of 5.5 cm, and suffered skin

The classification of reconstruction by distraction osteogenesis using bone transport (shown in tibia) or shortening distraction (shown in femur): type 1, diaphyseal reconstruction (a); type 2, metaphyseal reconstruction (b); type 3, epiphyseal reconstruction (c); type 4, subarticular reconstruction (d); and type 5, arthrodesis (e).
necrosis after wound closure. This was treated conservatively, allowing the wound to granulate during the distraction phase. One patient with osteosarcoma in the distal femur sustained a fracture of the regenerated callus which was treated by a cast for six weeks. The function of the affected limb was rated excellent in two patients and good in the other.

In the group in which treatment was combined with an intramedullary nail, an Ilizarov apparatus was used for two patients and a unilateral lengthener for four. A Russell-Taylor nail was used in five patients and a Huckstep nail in one. The mean external fixation index was 24.0 days/cm
and the distraction index 18.3 days/cm (14.2 to 23.4). One patient developed a deep infection which was treated by removal of the lengthener, irrigation, and intravenous antibiotics when bone transport had been completed. The function of the affected limb was rated excellent in two patients, good in three, and fair in one (Table I).

The mean external fixation and the distraction indices for the seven patients who had chemotherapy during distraction were 35.6 days/cm and 12.6 days/cm, respectively. In the 12 patients who did not receive chemotherapy these were 32.7 days/cm and 20.4 days/cm. There was no statistically significant difference for the external fixation index (p = 0.56, Student’s t-test).

No local recurrence of tumour was seen. Fifteen patients are currently free from disease and one patient with a stage-IIIB malignant fibrous histiocytoma is alive but has metastases. Two patients with stage-IIIB osteosarcoma and one with Ewing’s sarcoma have died from metastatic disease.

Classification of reconstruction with distraction osteogenesis (Fig. 2). We have classified reconstruction with distraction osteogenesis into five types based on the location of the defect after resection of the tumour. Type 1. Diaphyseal reconstruction. Type 2. Metaphyseal reconstruction. Type 3. Epiphyseal reconstruction. Type 4. Subarticular reconstruction. Type 5. Arthrodesis.

In type 1 the diaphyseal defect is reconstructed by bone transport or shortening-distraction (Fig. 3). To reconstruct the metaphyseal defect in type 2 Ilizarov wires or half pins for fixation may be used through the remaining epiphysis. In addition to bone transport or shortening-distraction, the...
A metaphyseal defect may be reconstructed with a bone cylinder from the diaphysis, filling the defect by bone transport (Fig. 4). Type 3 includes defects of the metaphysis and unilateral defects of the epiphysis. Type-3 metaphyseal defects are reconstructed by shortening the diaphysis or by using a bone cylinder from the diaphysis. A unilateral defect of the epiphysis is repaired with the articular surface of the ipsilateral patella and a strut graft from the iliac crest. The diaphyseal defect is then filled in by bone transport. When the defect has been shortened, a standard lengthening procedure is performed at the diaphysis (Fig. 5).

The type-4 procedure is used for reconstruction of subarticular defects. We have previously described this for the treatment of giant-cell tumours in the proximal tibia, and it may also be used at the distal tibia. Articular cartilage with or without some subchondral bone is left in situ after excision of the tumour, and Ilizarov wires cannot be applied through the epiphysis. A bone cylinder is taken from the diaphysis and fixed by wires to the remaining lateral or medial wall. The newly-created diaphyseal defect is then filled by bone transport (Fig. 6).

In type-5 procedures arthrodesis is used to reconstruct defects after joint resection and to correct subsequent discrepancy of leg length (Fig. 7).

A unilateral external fixator is convenient for a type-1 reconstruction and for diaphyseal lengthening in a type-5 arthrodesis. An Ilizarov apparatus is useful for the fixation of epiphyseal or metaphyseal structures and for simultaneous bone lengthening in the management of reconstructions of types 2, 3 and 4.

We used the type-1 procedure in two patients, type 2 in six, type 3 in two, type 4 in six and type 5 in three. The mean external fixation index was 26.7 days/cm for type 1, 28.2 for type 2, 33.7 for type 3, 44.2 for type 4, and 28.4 for type 5.

**DISCUSSION**

Distraction osteogenesis has been widely used for the treatment of leg-length discrepancy, nonunion, traumatic bone defects, deformity, and osteomyelitis. Its use in the management of musculoskeletal tumours has not been studied in detail. It has been employed in the reconstruction of diaphyseal defects after excision of tumours and for arthrodesis after joint resection. Cañadell et al used distraction osteogenesis to expand the tumour-free margin and to preserve the epiphysis by physeal distraction.

We have used distraction osteogenesis to reconstruct defects in the metaphysis and epiphysis as well as in the diaphysis. We classified the procedures available into five types. Types 2, 3 and 4 were most often used, because tumours occur more often in a periarticular location. For high-grade sarcomas, type-2, type-3 and type-4 reconstructions are indicated for patients in whom excision of the tumour can be performed under effective preoperative chemotherapy in order to reduce the risk of local recurrence. Caffeine-assisted chemotherapy, which has resulted in a high rate of local control, has allowed minimalisation of the...
resection of healthy tissue and periarticular reconstruction for osteosarcoma. Joint preservation and periarticular reconstruction should be limited to those who respond well to preoperative chemotherapy and are expected to have total tumour necrosis on radiological evaluation or biopsy. The technique should not be used in those who respond poorly, because local recurrence will lead to a poor prognosis.

The external fixation index for type-4 subarticular reconstruction was significantly greater than for the other types because free, devitalised diaphyseal bone had been used to reconstruct the subarticular defect and it was difficult to apply intramedullary nailing. The type-3 reconstruction using an ipsilateral patella to replace the articular surface may result in osteoarthritic changes later, although a low incidence of this has been reported in the management of giant-cell tumours.\(^9\)

When maturation of regenerated bone is very slow, decreasing the distraction speed, delaying distraction, axial shortening,\(^16\) or direct-current stimulation\(^15\) may be used. The addition of an intramedullary nail\(^15\) is beneficial as a temporary measure. The combination of an intramedullary nail and distraction osteogenesis may reduce the period of treatment with a decrease in the incidence of wire or pin-track infections. The external fixation index can be reduced as the maturation index approaches zero. We therefore apply intramedullary nailing for distraction osteogenesis whenever feasible. A thin, stress-resistant intramedullary nail is appropriate for combined use to preserve the intramedullary blood supply and allow space for the insertion of wires or half pins. If shortening-distraction is applied, bone graft at the docking site is not necessary. Femoral shortening of about 10 to 15 cm can be achieved if wound closure is feasible. Careful attention should be paid to the shortening of the tibia because of circulatory disturbance, but bital defects can be satisfactorily treated by bone transport for extensive bone loss.\(^9\)

We performed distraction osteogenesis on seven patients who were having chemotherapy after the operation. Although this was expected to delay bone regeneration initially and to increase the distraction index, callus was successfully distracted at about 0.8 mm per day in our series. Only one patient had a deep infection. In patients with osteosarcoma, minimalisation of the surgical margin aimed at the preservation of healthy tissue with effective chemotherapy may give satisfactory results. The number of patients was small, however, and the effects of chemotherapy on distraction osteogenesis or on bone regeneration are still unknown.

Bony defects created by limb-salvage procedures may be reconstructed by a variety of methods but the incidence of complications such as fracture, nonunion, deformity, and infection is high,\(^19\)-\(^25\), and is directly related to the size of the graft and the use of chemotherapy.\(^20\) The use of allografts or autoclaved bone in combination with vascularised bone grafts has been subjected to preliminary trials.\(^26\),\(^27\) Even although we encountered ten complications in 19 patients all were managed successfully.

The living bone regenerated in distraction osteogenesis will eventually provide sufficient biomechanical strength, stability and durability. Although external fixation may be prolonged, reconstruction by distraction osteogenesis results in a stable leg, avoids complications associated with prosthetic or allograft replacement and provides attachment for ligaments, tendons, and muscles. In growing children, leg-length discrepancies may be corrected by distraction osteogenesis after they have matured or during the distraction after tumour excision. Expandable prostheses have been developed for this problem.\(^28\)

Distraction osteogenesis is beneficial for patients with a good long-term prognosis and for growing children. For patients with metastatic disease, prosthetic replacement after resection of the tumour will provide an early improvement in function and is indicated. Other techniques offer simpler and less time-consuming reconstruction for some bony defects, but distraction osteogenesis has a place in reconstruction after the excision of a tumour; it will become more attractive if the duration of the treatment can be shortened. No benefits in any form have been received or will be received from a commercial party related directly or indirectly to the subject of this article.
