The effect of increased stress on the patellar tendon

H. Tohyama, K. Yasuda

From Hokkaido University School of Medicine, Sapporo, Japan

We performed a biomechanical and histological study to clarify the effect of stress enhancement on the in situ frozen-thawed patellar tendon of the rabbit as a tendon autograft model. We used 48 Japanese White rabbits divided into three groups. In group 1, the patellar tendon underwent in situ freeze-thaw treatment with liquid nitrogen to kill intrinsic fibroblasts. In group 2, after similar treatment, the medial and lateral portions were resected so that the cross-sectional area was reduced by a third. In group 3, after treatment, the cross-sectional area was reduced by a half. In groups 2 and 3, the stress in the tendon was calculated theoretically to be 150% and 200% of the physiological stress during locomotion.

Eight rabbits in each group were killed at three and six weeks, respectively. At three weeks, the mean values for the tensile strength of groups 2 and 3 were 113.7% and 75.7% of that of group 1, and at six weeks 101.2% and 57.4%, respectively. The tensile strength in group 3 was significantly lower than that in groups 1 and 2. The histological findings in group 2 were similar to those in group 1, although an acellular area appeared to be wider in the core portion compared with group 1 at each period. In group 3, the collagen bundles of the tendon were less organised than those of groups 1 and 2.

Our findings showed that stress enhancement affects the remodelling of the frozen-thawed patellar tendon and that excessively high stress reduces the mechanical properties of the tendon. This indicates that high stress on the patellar tendon autograft should be avoided during ligament reconstruction.

Received 7 March 2000; Accepted after revision 17 August 2001

The patellar tendon is commonly used as autograft in the reconstruction of ligaments. A number of histological and biochemical studies have shown that necrosis of fibroblasts in the transplanted tendon occurs sequentially during the early phase after such reconstruction. The graft is initially enveloped by vascular synovial tissue which initiates a revascularisation response that is accompanied by cellular proliferation. This revascularisation may take as long as 20 weeks to complete. Biomechanical studies have shown that the mechanical properties of the graft are extremely low at one year, compared with those of the original tendon, although they increase with time. Thus, there is an obvious discrepancy between the histological maturation and the mechanical restoration. In order to explain this discrepancy, we have suggested that various factors may affect the mechanical properties of the graft during the remodelling process after transplantation.

Hayashi and Yamamoto developed the marginal resection technique for the patellar tendon to increase the stress in the...
tendon. Using these techniques, we have isolated the effect of stress enhancement from that of other factors and attempted to clarify biomechanically and histologically this effect on the in situ frozen-thawed patellar tendon.

Materials and Methods

We used 48 mature female Japanese White rabbits weighing 3.4 ± 0.2 kg (mean ± sd) and aged 20 weeks or older. The experiment was carried out under the Rules and Regulations of the Animal Care and Use Committee of Hokkaido University School of Medicine. There were 16 animals in each of three groups. In group 1, the right patellar tendon underwent in situ freeze-thaw treatment with liquid nitrogen to kill intrinsic fibroblasts.

In group 2, the same treatment was carried out and the medial and lateral sixths were then resected so that the cross-sectional area of the remaining tendon was reduced by a third in order to enhance the stress. In group 3, the same treatment was undertaken followed by resection of the medial and lateral quarters so that the remaining cross-sectional area was halved. After operation the animals were allowed unrestricted activity in the cage. They were able to walk on all four limbs four or five days after surgery without impairment.

Eight rabbits in each group were killed using an overdose of barbital sodium under intravenous pentobarbital anaesthesia at three and six weeks after surgery. Based on power analysis with our pooled data of normal rabbit patellar tendons, five from each group of eight were used for biomechanical evaluation at each period. The analysis had indicated that statistical comparison between the five animals and normal values had a 20% probability of a type-II error (α power > 80%), when the difference in the tensile strength from the normal value was less than 10 MPa.

Three animals were used for histological examination at each period in each group. In addition, eight patella-patellar tendon-tibia complexes were randomly harvested from the left knees of all rabbits to obtain normal control data.

Operative procedure. All animals were operated on using sterile techniques under intravenous pentobarbital anaesthesia (0.05 mg/kg). The subcutaneous retinacula were incised longitudinally along the patellar tendon after the anterior aspect of the right knee had been exposed via a straight skin incision. The posterior surface of the patellar tendon was separated from the infrapatellar fat pad. Care was taken not to injure the fibres of the tendon. In group 1 a silicone rubber sheet was inserted between the tendon and the fat pad to make a bath with the tendon inside it. This bath was then filled with liquid nitrogen. The tendon was frozen for one minute and then thawed by pouring physiological saline solution into the bath. In group 2, after the right patellar tendon had undergone the same freeze-thaw treatment, the cross-sectional area of the whole tendon was measured in situ using an area micrometer with an 8 mm wide slot under a compressive stress of 0.12 MPa. The area micrometer is described in detail under 'mechanical testing'. Measurement of the cross-sectional area was performed again after the lateral and medial sixths of the tendon had been resected. We used the cross-sectional area micrometer with a 6 mm wide slot for the narrowed patellar tendon in group 2. The medial and lateral edges of the tendon were resected until the cross-sectional area became 66% to 67% of the original cross-sectional area. Care was taken to avoid damaging the sites of insertion and the remaining tendon. Theoretically, 150% of the physiological stress was applied in group 2. Group 3 was treated in the same way as group 2 except that the cross-sectional area of the tendon was reduced by 49% to 51%. Theoretically, 200% of the physiological stress was applied to the remaining tendon in group 3. The ratio of the cross-sectional area of the remaining tendon to that of the original tendon was 66.9 ± 1.5% and 50.1 ± 0.3% in groups 2 and 3, respectively. In each group, the fascia and skin were closed with interrupted monofilament nylon sutures.

Mechanical testing. The hind limbs were resected immediately after the death of the animal. They were wrapped in sheets of gauze soaked with physiological saline and stored in air-tight bags at -32°C until mechanical testing. Before testing, each specimen was thawed overnight at 4°C. The patella-patellar tendon-tibia complex was dissected from each limb. Care was taken to keep the patellar tendon moist with physiological saline at all times.

Using an area micrometer, we measured the cross-sectional area of each tendon at three different positions (the middle and 5 mm proximal and distal to the middle). The area micrometer has an 8 mm wide and 5 mm thick rectangular slot and a plunger which inserts into the slot. The tendon was placed in the slot, and the plunger was inserted and pressed against the tendon with a constant compressive
stress of 0.12 MPa applied for two minutes. This stress compressed the tendon to fill the slot while the thickness of the tendon was measured by the micrometer. The cross-sectional area was calculated by multiplying the width of the slot by the thickness. It was represented by the mean of three values obtained from the three different positions. The length of the tendon was defined as the distance from the distal end of the patellar attachment to the proximal end of the tibial attachment. This length was measured on the surface of the tendon by a digital vernier caliper, while the tendon was suspended with a 50 g calibration weight.

For evaluation of the mechanical properties of the tendon, we narrowed it in order to prevent failure at its sites of insertion during the tensile test, because the entire normal substance of the tendon was stronger than the bone at these sites. The medial and lateral thirds were removed using a specially designed cutter with two 15 mm long stainless-steel razor blades, 3.5 mm apart. Subsequently, the cross-sectional area of the remaining tendon was measured using an area micrometer with a 4 mm wide rectangular slot. The patella and the tibia were cast in aluminium pots using PMMA resin. A stain (Nigrosine) was used to draw two stained lines on the video image into an output voltage. Thus, the strain in the midsubstance of the tendon could be determined during tensile loading, independent of elongation at the sites of insertion.

The specimen was immersed in physiological saline at 37°C during testing. After applying a preload of 0.5 N for ten minutes, it was subjected to ten loading-unloading cycles between elongation limits of 0 mm and 0.5 mm at a rate of 20 mm/min and then stretched to the point of failure at the same rate. During tensile testing, the load and the displacement between the two markers with the video dimension-analyser system which could convert the distance between stained lines on the video image into an output voltage. From the load-displacement relation, a stress-strain curve was obtained in which stress was calculated by dividing the tensile load by the cross-sectional area, and strain by dividing displacement by the initial gauge length. The elastic modulus, the tensile strength, and the strain at failure were then determined.

**Histological examination.** The patella-patellar tendon-tibia complexes were harvested from the hind limbs immediately after the death of the animal and the surrounding tissues carefully removed. The specimens were sectioned along the longitudinal axis of the tendon. Each complex was then fixed in a 10% buffered formalin solution, decalcified, cast in a paraffin block, stained with haematoxylin and eosin and examined by light microscopy.

**Statistical analysis.** We used two-way analysis of variance (ANOVA) to assess the effects of treatment and time on the cross-sectional area, the length, the elastic modulus, the tensile strength and the strain at failure. Fisher’s PLSD test was applied for post-hoc multiple comparisons. The limit of significance was set at p = 0.05.

**Results**

**Tissue dimensions.** Two-way ANOVA showed a significant difference in the cross-sectional area with respect to group and to time (among groups, p = 0.001, power (1-β) = 1.000; between time periods, p = 0.001, power (1-β) = 0.985; interaction, p = 0.705, power (1-β) = 0.099). The cross-sectional area at six weeks was significantly greater than that at three weeks (p = 0.001). The mean values for the area in group 2 were 68.3% and 67.3% of those of group 1 at three and six weeks, respectively, which was significant (p = 0.001). The mean values for the area in group 3 were 60.1% and 57.9% of those of group 1 at three and six weeks, respectively (p = 0.001) and were also significantly smaller than in group 2 (p = 0.008). Regarding the length of the tendon, we failed to show a significant difference in the three groups or between three and six weeks (among groups, p = 0.058, power (1-β) = 0.552; between time periods, p = 0.810, power (1-β) = 0.056; interaction, p = 0.502, power (1-β) = 0.152) (Table I). The mean values for the length in group 2 were 96.1% and 100.5% of those of group 1 at three and six weeks, respectively, and those in group 3 were 102.4% and 111.6% of group 1 at three and six weeks, respectively.

**Mechanical properties.** All specimens failed between the gauge lines in the tendon substance. Figure 2 shows the stress-strain curves of the three groups at each period compared with the control curve. The curve of group 3 had the smallest slope and the lowest peak.

At three weeks, the mean values of tensile strength for groups 2 and 3 were 113.7% and 75.7% of group 1 (Table I).

**Table I.** Mean (± SD) cross-sectional area and length of the patellar tendon at three and six weeks compared with the control.

II) and at six weeks 101.2% and 57.4%, respectively. Two-way ANOVA showed a significant difference with respect to group and time period (among groups, \(p = 0.019\), power (1-\(\beta\)) = 0.735; between time periods, \(p = 0.001\), power (1-\(\beta\)) = 0.969; interaction, \(p = 0.070\)). The mean values for the modulus of group 3 at three and six weeks were 57.3% and 59.6% of that of group 1, while of group 2 they were 104.4% and 96.0%, respectively (Table II). The differences in the mean elastic modulus between groups 3 and 1 were -49 MPa (95% CI -528 to 430 MPa, \(p = 0.819\)) and -270 MPa (95% CI -543 to 4 MPa, \(p = 0.053\)) at three and six weeks, respectively, while between groups 2 and 1 the values were 44 MPa (95% CI -552 to 639 MPa, \(p = 0.870\)) and -25 MPa (95% CI -263 to 213 MPa, \(p = 0.814\)). The modulus at six weeks was significantly lower than that at three weeks (\(p = 0.001\)).

We failed to show a significant difference in the elastic modulus among the groups (\(p = 0.243\), power (1-\(\beta\)) = 0.178), but there was a significant difference between three and six weeks (\(p = 0.001\), power (1-\(\beta\)) = 0.969). We also failed to show a significant interaction effect between group and time (\(p = 0.862\), power (1-\(\beta\)) = 0.070). The mean values for the modulus of group 3 at three and six weeks were 57.3% and 59.6% of that of group 1, while of group 2 they were 104.4% and 96.0%, respectively (Table II). The differences in the mean elastic modulus between groups 3 and 1 were -49 MPa (95% CI -528 to 430 MPa, \(p = 0.819\)) and -270 MPa (95% CI -543 to 4 MPa, \(p = 0.053\)) at three and six weeks, respectively, while between groups 2 and 1 the values were 44 MPa (95% CI -552 to 639 MPa, \(p = 0.870\)) and -25 MPa (95% CI -263 to 213 MPa, \(p = 0.814\)). The modulus at six weeks was significantly lower than that at three weeks (\(p = 0.001\)).

ANOVA failed to show any significant difference in strain at failure among groups or between time periods (among groups, \(p = 0.243\), power (1-\(\beta\)) = 0.278; between time periods, \(p = 0.812\), power (1-\(\beta\)) = 0.056; interaction, \(p = 0.387\), power (1-\(\beta\)) = 0.195) (Table II).

**Histological findings.** In group 1, some cells with an ovoid or spindle-shaped nucleus were observed in the posterior quarter of the tendon at three weeks, while none was seen in the core portion. Collagen bundles of group 1 were longitudinally aligned with a distinct crimped pattern (Fig. 3a). At six weeks, some cells with a rod-like nucleus occasionally appeared, while a number of cells with an ovoid or spindle-shaped nucleus were dispersed throughout the patellar tendon. The crimped pattern of the collagen bundles was less distinct compared with that seen at three weeks (Fig. 3b). In group 2, the histological findings of the collagen bundles and the shape of the cell nucleus were

Photomicrographs of longitudinal sections of core portions of the patellar tendon. Figure 3a – Group 1 at three weeks. Some cells with an ovoid or spindle-shaped nucleus are present in the posterior quarter of the tendon (lower area). Figure 3b – Group 1 at six weeks. There are some cells with a rod-like nucleus, while a number with an ovoid or spindle-shaped nucleus are dispersed. Figure 3c – Group 2 at three weeks. The acellular area appears wider compared with group 1 at three weeks (Fig. 3a). Figure 3d – Group 2 at six weeks. The acellular area appears wider compared with group 1 at six weeks (Fig. 3b). Figure 3e – Group 3 at three weeks. There is fragmentation of the collagen bundles (lower area). Figure 3f – Group 3 at six weeks. The collagen bundles are less orientated compared with groups 1 and 2 (Figs 3b and 3d) (haematoxylin and eosin, bar = 200 μm).
similar to those of group 1, although an acellular area appeared to be wider in the core portion at each period (Figs 3c and 3d). In group 3, fragmentation of collagen bundles was observed in the tendon at three weeks. Some cells with an ovoid nucleus were seen in the posterior quarter of the tendon which had the same appearance as group 1, while cells with a spindle-shaped nucleus were less frequently observed (Fig. 3e). At six weeks, the collagen bundles of group 3 were less orientated compared with those of groups 1 and 2 (Fig. 3f). At each period, cells with an ovoid nucleus were often seen in disorientated collagen bundles, although no cells with a rod-like nucleus were observed in the tendons of group 3.

Discussion

In our study, doubling the physiological stress resulted in a deterioration of the tensile strength of the in situ frozen-thawed patellar tendon and disorganisation of the collagen bundles. The increased stress decreased the mean elastic modulus of the tendon to 57% of that of the in situ frozen-thawed tendon, although we failed to demonstrate a statistical significance. Our study has shown that stress enhancement which exceeds a certain level affects the remodelling of the in situ frozen-thawed patellar tendon.

This model has important advantages such as no disturbance to the sites of attachment of the tendon and no alteration of its mechanical environment.9-12,15

There are a few limitations in our study regarding the methodology. The first is that we used the in situ frozen-thawed tendon as an autograft model. Because this is an extra-articular autograft model, the results cannot refer to the intra-articular autograft. The second limitation is that we could not quantify precisely the degree of the enhanced stress in the patellar tendon throughout the experimental period. Hayashi et al16,17 measured the in vivo tensile load of the rabbit patellar tendon which had been narrowed by the same method as that used in our study using a buckle transducer. They showed that there were no significant differences in the peak load between the narrowed and normal patellar tendons. This strongly suggests that the stress in the narrowed patellar tendon is enhanced. If the physiological load is applied to the narrowed tendons during locomotion, the stress value is calculated theoretically to be 150% and 200% of the physiological level in groups 2 and 3, respectively, during the early phase after surgery. Although the cross-sectional area of the remaining tendon increased with the passage of time, that in groups 2 and 3 remained 67.3% and 57.6% of that in group 1 at six weeks, respectively. Therefore we can calculate theoretically that the stress value in groups 2 and 3 at six weeks is 149% and 174% of that in group 1, respectively. The third limitation of our study is that we resected the medial and lateral margins of the tendon in order to reduce the cross-sectional area in groups 2 and 3. It is possible that this surgical invasion may affect the tendon although care was taken to avoid damage to the sites of insertion and the remaining tendon. For the tendon in group 2, however, compared with group 1, we did not find detrimental effects of this procedure on the mechanical properties. We believe therefore that the effect of the surgical invasion was negligible.

Two mechanisms are possible to explain the detrimental effects of excessive stress enhancement on the mechanical properties of the frozen-thawed tendon. The first is that excessive stress enhancement may cause deterioration of the extracellular matrix in the tendon, specifically fatigue failure of collagen fibres. The second is that it may affect extrinsic cells which infiltrate the tendon after the intrinsic fibroblast necrosis, and that biological activity of the extrinsic cells may reduce the mechanical properties of the tendon. Hannafin et al19 studied the effect of tensile load on the canine flexor tendon using the in vitro tissue explant system. They reported that the application of a 1 N tensile load resulted in fibroblast necrosis and loss of the crimped pattern of the collagen, although the application of a 0.5 N tensile load did not affect the tendon. These facts imply that excessive stress directly damages the structure of the collagen of the tendon and they support the first potential mechanism. Many in vitro studies using cultured cells have shown that stress generally stimulates collagen synthesis of fibroblasts, osteoblasts and endothelial cells.23-25 These studies do not support the second mechanism. In order to clarify the mechanism of the detrimental effects of excessive stress enhancement on the frozen-thawed patellar tendon, in future studies they should be isolated from those on extrinsic cells.

Our histological findings indicate that moderate stress enhancement slightly delayed the infiltration of extrinsic cells from surrounding tissues into the tendon. Yoshiya et al11 showed that a patellar graft initially fixed at a tension of 39 N has poor vascularity compared with that fixed at 1 N. Such poor vascularity induced by high stress may delay the infiltration of extrinsic cells into the tendon after intrinsic fibroblast necrosis.

It is important to compare the effect of stress enhancement to that of stress deprivation on the frozen-thawed patellar tendon, when we consider the effect of the mechanical environment on the graft. We have previously reported the effect of stress deprivation using the frozen-thawed patellar tendon which was also used in this study.9,10 Complete stress-shielding decreases the tensile strength of the frozen-thawed patellar tendon to 17% and 28% of that of the physiologically stressed tendon at three and six weeks, respectively. The present study showed that excessive stress enhancement decreased the tensile strength of the frozen-thawed patellar tendon to 76% and 57% of that of the physiologically stressed tendon at three and six weeks, respectively. Thus, we find that excessive stress enhancement decreased the mechanical properties of the frozen-thawed patellar tendon more slowly than excessive stress deprivation. We consider that the mechanism of the deterioration of the frozen-thawed patellar
tendon may be different in stress enhancement and deprivation.

We also compared the effects of stress enhancement on the extra-articular autograft model with those on the intra-articular model. Katsuragi et al. evaluated the effects of stress enhancement on the mechanical properties of the frozen-thawed anterior cruciate ligament using a canine model. They reported that excessive stress enhancement did not affect the mechanical properties of the frozen-thawed ACL at six weeks, but that it significantly decreased them at 12 weeks. In addition, they also stated that excessive stress enhancement did not affect the cross-sectional area of the frozen-thawed ligament until 12 weeks. These findings are similar to those obtained in our study, although significant differences appear earlier in the extra-articular than in the intra-articular model. The similarity of the findings supports the main result of our study that excessive stress enhancement significantly decreases the mechanical properties of the frozen-thawed tissues as autograft models.
