CASE REPORT

Injury to the axillary artery, a complication of fixation using a locking plate

The proximal humerus internal locking system is an internal fixation device consisting of a low-profile plate and locking screws, which is used for the fixation of three- and four-part fractures of the proximal humerus. We describe a case in which the screws cut out of the humeral head causing injury to the axillary artery necessitating urgent removal of the implant.

Fractures of the proximal humerus are common among the elderly with osteoporosis. Management of three- and four-part fractures remains controversial because of the disappointing results from all methods of treatment. Previously used devices for internal fixation have been rudimentary and prone to failure, even leading to migration of metal with consequent complications. The proximal humerus internal locking system (Philos; Synthes Limited, Hertfordshire, England) consists of a low-profile plate with proximal locking screws which has allowed the fixation of fractures that were previously considered to be inoperable or suitable only for hemiarthroplasty. We describe a case which demonstrates the potentially serious consequences of the device cutting out of the humeral head.

Case report

A 67-year-old woman presented with a widely displaced fracture of the left humeral neck following a fall (Fig. 1). There was no neurological deficit and the radial pulse was preserved. Internal fixation was performed the following day, using a short Philos plate held by six proximal and three distal locking screws (Fig. 2). A collar-and-cuff sling was applied and assisted movement under supervision of a physiotherapist was allowed, but patient compliance was limited. A radiograph taken 12 days after the operation showed that the screws had cut out from the humeral head allowing displacement of the plate which remained attached to the humeral shaft (Fig. 3). It was decided to undertake a revision procedure using a hemiarthroplasty. There was a tense haematoma in the deltopectoral interval and around the displaced implant. After removal of the proximal locking screws and plate there was considerable deep haemorrhage. Control of the axillary artery was achieved with vascular clamps on either side of a tear in the artery 0.5 cm long. This was repaired with a running suture of 5/0 nylon. A cemented hemiarthroplasty was then introduced. When the clamps were released there was further bleeding from another, more distal perforation in the axillary artery. This was also repaired. During this operation she received six units of blood and four units of fresh-frozen plasma.

Anteroposterior radiograph showing the fracture at presentation.
Throughout the following evening, the swelling around the left shoulder continued to increase. Pain and tachycardia indicated continuing haemorrhage and she was therefore taken back to theatre where a vascular surgeon explored the axillary artery and placed additional sutures at one of the previous sites of repair. Further transfusion was necessary with ten units of blood and eight units of fresh-frozen plasma. After 36 hours in intensive care, she was transferred to the orthopaedic ward. At that stage, the left arm was well perfused and there was no neurological deficit. A tense haematoma, developing on the left anterior chest wall, was investigated by aortic-arch angiography. There was no evidence of a false aneurysm or arterial narrowing (Fig. 4). She was discharged from hospital 20 days after the last exploration. At outpatient review five weeks later, the hemiarthroplasty was found to have dislocated anteriorly resulting in poor function, but only minimal discomfort. She elected to have no further surgery.

Discussion
Vascular injury related to surgery for fractures of the proximal humerus is rare. A false aneurysm of the axillary artery has been reported after intramedullary nailing of a fracture of the proximal humerus locked by a long proximal screw.\textsuperscript{11} The propensity for metal placed in the shoulder to migrate is well recognised.\textsuperscript{7-9} Wires have been known to enter the thoracic cavity and to be located in the heart.\textsuperscript{7}

The fixation of complex proximal humeral fractures may be difficult because of the quality of bone and the shortcomings of the implants that are available. The Philos system, by virtue of the divergent locking screws, offers increased security of fixation particularly in the presence of osteoporosis. The technique is critical and requires reduction of the fracture before any screws are inserted, placement of the plate at an appropriate level in order to avoid subacromial impingement and to allow for optimal placement and purchase of screws in the cancellous bone of the humeral head which is the weak point of the fixation. Secure fixation allows early movement and return of function.

In this case, screws probably of inadequate length, cut out of the osteoporotic humerus so that the screws could migrate medially towards the neurovascular bundle (Fig. 3).
The minor lacerations in the axillary artery were consistent with perforation by the sharp tips of the screws. Control of bleeding proved to be difficult and continued even after the second attempt with the development of a hematoma in the chest wall. Angiography showed no evidence of a false aneurysm or communication with the axillary artery. Subsequent anterior dislocation of the hemiarthroplasty was attributable to failure of the repair of the tuberosities. At the present time, 12 months after the initial procedure, the pain is tolerable and further surgery is not under consideration.

When using such devices for internal fixation of this fracture, the surgical technique has to be meticulous to achieve reduction and to ensure that the hold of the screws in bone is secure.
