CASE REPORT

A total hip replacement infected with *mycobacterium bovis* after intravesicular treatment with Bacille-Calmette-Guérin for bladder cancer

O. Reigstad,
P. Siewers

From the University of Oslo, Oslo, Norway

An 86-year-old male presented with a loose total hip replacement (THR) ten years after implantation. At revision for anticipated aseptic loosening, watery pus was found in the joint and Bacille-Calmette-Guérin (BCG) was seen on culture. The bacterial strain was identified and was identical to the BCG used in the intravesicular treatment of superficial bladder carcinoma in this patient ten months earlier. After revision he received a full course of antituberculous treatment.

The clinical and radiological results were excellent after follow-up for 30 months with his uncemented THR showing satisfactory incorporation. His inflammatory markers were normal and his Harris hip score was 95 points.

The diagnosis of a tuberculous infection can be easily missed, but must be considered, especially if sterile pus is encountered.

Revision of a total joint replacement for suspected aseptic loosening will occasionally reveal unexpected infection. Identification of the micro-organism has implications for treatment. Worldwide, tuberculosis is a major infectious disease and an increase in its incidence is anticipated in industrialised countries. We report an unusual case of tuberculous infection occurring in a total hip replacement (THR).

Case report

An 86-year-old man presented with pain in the groin ten years after a successful primary THR for osteoarthritis (OA). He had been diagnosed with a papillary tumour in the bladder ten months previously and the lesion had been treated by transurethral resection and intravesicular chemotherapy with 80 mg of epirubicin (Pharmorubicin; Pfizer, New York City, New York). Two months after surgery, weekly treatment with intravesicular Bacille-Calmette-Guérin (BCG) (Onco-Tice; Organon, Kenilworth, New Jersey) had been started for a period of six weeks. After an interval of three months without treatment, he had a course for another three weeks, giving a total of nine intravesicular instillations. During the final six months of treatment, he had experienced increasing pain in the groin, especially when bearing weight on his THR and rotating the hip. Other than his bladder cancer, he was healthy, with a high level of activity including trekking, boat renovation and extensive gardening.

A radiograph showed an Exeter (Stryker-Howmedica, Kalamazoo, Michigan) cemented THR with radiolucent lines around the acetabular component and a fracture of the femoral cement mantle (Fig. 1).
We decided to perform a revision THR using uncemented components. Pre-operative blood tests were within the normal range except for the ESR, which was marginally elevated at 18 mm/hour (normal level 3 to 16) and the level of C-reactive protein (CRP) at 12 mg/l (normal level 0 to 12).

After incising the capsule, approximately 50 ml of thin watery yellowish pus was drained. Fluid and tissue biopsies were obtained and sent for culture and histological examination. Given the advanced age of the patient, we decided peroperatively to undertake a one-stage revision with implantation of an uncemented THR using a Kar (Depuy, Warsaw, Indiana) femoral component with a 28 mm chrome-cobalt head and a Trilogy (Zimmer, Warsaw, Indiana) acetabular component.

Sixteen days after operation, acid-fast bacilli were cultured and demonstrated histologically (Fig. 2). No other organisms were found.

Extensive investigation of the infecting organism using polymerase chain reaction (PCR), hybridisation and characterisation of the strain revealed that the Onco-Tice BCG strain used in the treatment of the superficial bladder carcinoma had been the causative organism of the infection. The sensitivities were confirmed and triple antituberculous treatment was started using rifampicin (600 mg), isoniazid (300 mg) and pyrazinamid (1.5 g) daily. The patient was mobilised and discharged after ten days. At six weeks after operation the erythrocyte sedimentation rate, C-reactive protein and white blood cell count were normal. Urine culture had failed to demonstrate tuberculosis, and cystoscopy and chest radiography were normal. After six months, the treatment was reduced to rifampicin and isoniazid, and then to isoniazid (200 mg) daily in isolation after one year. After two years, all antibiotic treatment was discontinued.

Post-operative radiographs at 3, 6, 12, 24 and 30 months (Fig. 3) showed a stable THR with increasing osseointegration and no lucencies.

The patient was able to tolerate the initial triple therapy without distress or disturbance of liver enzymes or renal function. He has remained free from pain and is mobile without crutches, returning to his former activities. At the final follow-up, his Harris hip score was 95 points.

**Discussion**

The weakened strain of living *Mycobacterium bovis* developed by Camille and Guérin in 19214 was intended for vaccination. The immunological effect through activation of the T-lymphocytes led to its use in the treatment of superficial bladder cancer in 1976.5

Intravesicular instillation of BCG and cytostatic medication at weekly intervals remain the principal treatment for non-invasive tumours.6,7 Side-effects comprise local irritation, immunological reactions, local infections and haematoagenous septicemia reported in almost every organ.8

Tuberculosis is one of the major diseases in the world, with approximately one third of the population infected, according to the World Health Organisation.2 The disease is attributable to three related organisms, mainly *Mycobacterium tuberculosis*, *M. bovis* and *M. africanum*. An increase in the number of serious cases is expected because
of the emergence of multi-resistant strains of the bacterium and HIV infections.

Reports of BCG or *M. tuberculosis* infection in joint replacements are rare. Guerra et al\(^9\) reported a BCG infection in a THR in which revision to an excision arthroplasty was performed. After an interval of three months, following a six-month course of antituberculous treatment, a bone biopsy revealed acid-fast bacilli. The risk of re-infection was considered to be substantial and further reconstruction was not performed. Marmor, Parnes and Dekel\(^10\) reported three patients with tuberculous-infected knee replacements, in two of whom loosening had occurred. Treatment was successful with two-stage revision and antituberculous medication. The remaining patient was managed with lavage and antituberculous treatment. No sign of re-infection was seen at follow-up after 18 months and five and seven years. In contrast to other bacterial infections in joint replacements it seems that the mycobacterium does not produce a biofilm on implants.\(^11\) The main problem is the slow reproduction of the bacterium and the subsequent need for long periods of antibiotic treatment.\(^12\) The risks associated with one- or two-stage revision are acceptable if appropriate antibiotics are administered but treatment must be continued for a period of at least six months. Both Guerra et al\(^9\) and Marmor et al\(^10\) reported initial false-negative results from bacterial culture. It is important to consider this diagnosis, especially if sterile pus is present. Supplementary and prolonged culture of the samples can reveal unexpected results.

We are grateful to Dr B. Von der Lippe, Ulleval University Hospital, for his helpful advice on the management of this patient.
