Subperiosteal resection of aneurysmal bone cysts of the distal fibula

F. O. Abuhassan, A. O. Shannak
From Jordan University Hospital, School of Medicine, Queens Rania Street, Amman 11942, Jordan

We describe the treatment by subperiosteal resection of an aneurysmal bone cyst in the distal fibula in eight patients and highlight the role of the periosteum in the regeneration of bone defects. The mean age of the patients was 13.5 years (12 to 17). Seven had an open growth plate. The mean size of the resected specimen was 5.12 cm (3.5 to 8.0). None of the patients received instillation of bone marrow, autogenous bone graft, allograft or any synthetic bone substitutes.

All had complete regeneration of the bone defect within three to nine months, with no joint instability or recurrence.

The mean length of follow-up was 11.5 years (2 to 18). At the final follow-up there was no difference in the range of movement, alignment or stability of the ankle when compared with the opposite side. The periosteum played a major role in the complete filling of the bone defects and avoided the morbidity of other techniques.

The distal fibula is an uncommon site for an aneurysmal bone cyst. Total resection of the lateral malleolus may produce a deformity and compromise the stability of the ankle.1 The main aims of treatment are to eradicate the cyst, avoid local recurrence, prevent damage to the growth plate, avoid subsequent valgus deformity and maintain the stability of the ankle.2-5 Curettage and bone grafting have been the usual methods of treatment4 for accessible cystic lesions.6,7 Various methods have been proposed for the reconstruction of the ankle after total resection of the distal fibula.1,4,5,8

The complications of curettage and grafting include a high rate of recurrence, injury to the growth plate, limb-length discrepancy and joint instability.9 Resection of the distal fibula for benign bone lesions is an accepted practice, but necessitates reconstruction of the distal tibiofibular joint. It should be reserved for aggressive or recurrent juxtaphyseal lesions, since there is an increased morbidty following multiple procedures, problems with implants and prolonged immobilisation.4

We describe our experience of the treatment by subperiosteal resection of an aneurysmal bone cyst of the distal fibula in eight young patients without a bone graft.

Patients and Methods

There were five girls and three boys with a mean age of 13.5 years (12 to 17) who were treated between 1988 and 2006. The lesions were located on the right side in five and on the left in three.

Local pain was the main symptom in all the patients and was associated with unrelated previous injuries in three. Two had a limp and a localised tender mass was palpable in three. The mean duration of symptoms before diagnosis was 4.9 months (2 to 7). When first seen none of the patients had abnormal alignment or limitation of movement of the ankle. Seven had a visible open growth plate on plain radiographs and in one the growth plate was closed.

Anteroposterior and lateral plain radiographs of the ankle were taken in all the patients. None had MRI or CT. The clinical and radiological details are given in Table I. Radiological evaluation described the relationship of the cysts to the growth plate and was classified according to the system of Campanacci, Capanna and Picci,10 and Capanna et al11 based on the anatomical location. There were five types of lesion with types 1 and 2 corresponding to central forms and types 3 to 5 to peripheral forms. The activity was graded by the system of Capanna et al,11 which included three stages, namely aggressive, active and inactive.

The diagnosis was made by the appearance of the fluid drained from the cyst after pre-operative aspiration, the typical radiological
findings of ballooning of the distal fibula and by histological examination of the resected lesion.

The mean follow-up was 11.5 years (2 to 18). All the patients had the same surgical procedure of subperiosteal resection without reconstruction. None received instillation of bone marrow, autogenous bone graft, an allograft or any synthetic bone substitutes.

At follow-up clinical and radiological evaluation of the extent of regeneration at the site of resected lesion, physeal growth, alignment, the range of movement of both ankles and recurrence was recorded. Conventional radiography was carried out at four, eight and 12 weeks, at six months and then annually.

Operative technique. Under general anaesthesia with a tourniquet applied to the thigh, the cyst was removed in one piece by subperiosteal resection involving all the cortices without leaving a strut of normal bone.

A lateral longitudinal incision was made over the centre of the lesion down to the periosteum. The periosteal sheath was incised longitudinally and raised gently with a periosteal elevator from the underlying cystic lesion and marked by silk structures (Fig. 1). If the end of the cyst was more than 0.5 cm from the growth plate, multiple 2.5 mm diameter drill holes were made away from the growth plate and the bone ends cut by a fine osteotome. The edge of the cyst near the growth plate was removed by a bone nibbler...
and a fine curette, with careful preservation of the growth plate. The subperiosteal shell of the bone with the cyst was removed in one piece as far as its attachment to the margins of the remaining normal bone without leaving any bony fragments in the defect. The medullary canal proximal to the remaining bone defect was opened using a 3 mm Kirschner (K)-wire to allow free communication with the defect. The thick periosteal sheath around the defect was then sutured using 3/0 Vicryl to obtain a tight closure. The remaining distal part of the fibula was fixed to the tibia by a 1.5 mm K-wire in all cases in which there was an open growth plate (Fig. 2a).

The skin was closed by subcuticular sutures, with no wound drainage. The limb was immobilised in a plaster cast with partial weight-bearing allowed. After two months the cast and K-wires were removed and the patients were allowed full movement and weight-bearing as tolerated. They were able to participate in sports after six months.

**Results**

The mean size of the resected cysts was 5.2 cm (3.5 to 8.0). Using the classification of Campanacci et al. all the lesions were type 2 and were active. At the final follow-up there was no difference in the mean range of movement in the ankle compared with that of the opposite side. No lesions recurred and there was no injury to the growth plate or evidence of joint instability. Shortening of 2 mm to 3 mm was seen at the distal fibula in comparison with the normal side, but this did not affect the range of movement or the stability of the ankle.

Bone began to regenerate three weeks after resection following the course of the closed periosteal tube (Fig. 2b). Complete healing of the defect occurred at a mean of 4.1 months (3 to 9). In one patient with a closed growth plate bony consolidation was not achieved for nine months but in those with an open growth plate this occurred at a mean of 3.3 months (3 to 4).

None of the defects showed evidence of delayed or non-union. One patient had delayed incorporation of the regenerate at the site of proximal resection after an electric saw had been used to cut the bone ends. No patient had a fracture of the regenerative bone.

At the final follow-up all patients had normal function of the treated limb without discomfort and had resumed their normal activities. Healing was obtained by filling and ossification of the defect.

**Discussion**

Aneurysmal bone cysts are benign, non-neoplastic, expansile, osteolytic lesions of multifactorial aetiology, composed of blood-filled spaces separated by connective tissue septa containing fibroblasts, osteoclast-type giant cells and reactive woven bone. Their precise pathogenesis is unclear, although suggestions include a post-traumatic reaction to reactive vascular malformation or a genetic predisposition.

The incidence is 1.4 per 100,000 individuals, with 80% of cases seen before the age of 20 years. The peak incidence is in the second decade of life. They occur more commonly in the metaphysis of long bones, especially the tibia, humerus and femur.

The reported incidence of lesions in the distal fibula varies between 7.1% and 16.4%. The management of an aneurysmal bone cyst depends on the age of the patient, the location, the size and the aggressiveness of the lesion. The clinical and pathological behaviour in younger patients does not seem to be more aggressive than that in older children, with no statistically significant differences between the age groups and the rate of recurrence.

Since the origin and growth of aneurysmal bone cysts are controversial, a variety of treatments has been described, but a relatively high rate of local recurrence has been recorded depending on the method used. The most common treatments are curettage, resection, intra-cystic injections and embolisation. Recurrence is more common in active and aggressive lesions and occurs at a mean of 7.6 months. This has been attributed to incomplete curettage of the primary soft-tissue component because of the reluctance of the surgeon to perform a sufficiently extensive procedure near an open growth plate, especially in the leg. A mitotic index of seven or more per 50 fields (x 750) is associated with a higher rate of recurrence than a lower mitotic index.

In aggressive lesions the rate of recurrence using curettage with or without bone grafting varies between 18% and 59%. Adjunctive therapy such as liquid nitrogen, phenol, the use of polymethylmethacrylate and irradiation
has been used, but is associated with increased morbidity and no apparent decrease in the rate of local recurrence compared with curettage alone.\textsuperscript{9,13}

Marginal en bloc resection may be adopted in an eccentric lesion or in an expandable bone such as the fibula, rib, pubic ramus, metacarpal or metatarsal. This procedure has little morbidity and a minimal risk of recurrence.\textsuperscript{3,6,22,25,26}

Resection of the lesion has the lowest association with recurrence while excision through the margin has consistently decreased the rate of local recurrence.\textsuperscript{10,27-29} Despite the rate of recurrence in various methods of treatments, more aggressive operative intervention does not appear to be indicated and recurrence can be successfully treated by repeated extended curettage and bone graft.\textsuperscript{19,30}

It is important to preserve the growth plate, especially in young children, even if the lesions are likely to recur.\textsuperscript{25} When growth of the lower fibular physis is arrested, a valgus deformity of the ankle may develop, the degree of which depends on how many years of potential growth remain.\textsuperscript{31} The risk of secondary valgus deformity is insignificant between ten and 12 years.\textsuperscript{31} If curettage and bone grafting have been performed carefully, the growth plate is unlikely to be affected.\textsuperscript{2,24} In children with an open growth plate, the main problems are at the level of the distal cut with the risk of iatrogenic damage or incomplete resection and the subsequent need for reconstruction.\textsuperscript{2} In younger children, the lesion should be resected at the edge of the growth plate.\textsuperscript{3} All our patients were treated meticulously by resection of the cyst near the edge of the physis without any residual damage.

Recurrence of distal fibular lesions after curettage and bone grafting may occur for which resection is the only successful method of treatment.\textsuperscript{8} An increased morbidity, however, must be considered after such a procedure.\textsuperscript{9,18}

The technique used in our study avoided the use of bone graft from the iliac crest, allograft bone or synthetic bone substitutes. Subperiosteal resection has been previously described as a primary method of treatment of lesions of the distal fibula, but there was no regeneration of the bone defect.\textsuperscript{32} Autologous tibial graft has been suggested after total subperiosteal resection of solitary bone cysts of the humerus in order to bridge the defect and to decrease local recurrence.\textsuperscript{33} No previous study has highlighted the effectiveness of the periosteum alone in forming new bone after resection of lesions of the distal fibula.\textsuperscript{27,32} We assume that the inner layer of the periosteum has an osteoblastic capability which allows invasion of the haematoma in the tightly sutured periosteal tube by osteoprogenitor cells. Healing of the remaining defect occurred in a progressive manner which suggests that osteogenesis occurred initially at the margins of the cavity and moved toward its centre over the following weeks. Progressive calcification and ossification followed and the lesion was transformed into a solid bony mass.

The location of the fibular lesion near the ankle may cause instability, recurrence or growth arrest,\textsuperscript{12} but we did not encounter these problems. Although age, the location of the lesion, and its size have been suggested as risk factors for local recurrence in aneurysmal bone cysts,\textsuperscript{9,24} the subperiosteal resection totally removed the pathological lesion. The mean healing time after traditional surgical treatment is 11.6 months (8 to 15) whereas after injection with steroids or bone marrow it is 13.9 months (15 to 18).\textsuperscript{33} In our patients the healing time was much shorter within a mean of 4.12 months (3 to 9).

The main advantage of subperiosteal resection is the complete regeneration of the bone defect and the absence of local recurrence. This can be attributed to the presence of a thick periosteum with substantial regenerative capacity. Preservation of the integrity of the periosteum after subperiosteal resection constitutes a valuable matrix for bone regeneration in children and young adolescents. It plays a major role in the complete filling of the bone defects and avoids the morbidity associated with other techniques.
