The Andersson lesion in ankylosing spondylitis

DISTINGUISHING BETWEEN THE INFLAMMATORY AND TRAUMATIC SUBTYPES

From Guri Hospital, Hanyang University College of Medicine, Kyunggi-do, Korea

A number of causes have been advanced to explain the destructive discovertebral (Andersson) lesions that occur in ankylosing spondylitis, and various treatments have been proposed, depending on the presumed cause. The purpose of this study was to identify the causes of these lesions by defining their clinical and radiological characteristics.

We retrospectively reviewed 622 patients with ankylosing spondylitis. In all, 33 patients (5.3%) had these lesions, affecting 100 spinal segments. Inflammatory lesions were found in 91 segments of 24 patients (3.9%) and traumatic lesions in nine segments of nine patients (1.4%). The inflammatory lesions were associated with recent-onset disease; a low modified Stoke ankylosing spondylitis spine score (mSASSS) due to incomplete bony ankylosis between vertebral bodies; multiple lesions; inflammatory changes on MRI; reversal of the inflammatory changes and central bony ankylosis at follow-up; and a good response to anti-inflammatory drugs. Traumatic lesions were associated with prolonged disease duration; a high mSASSS due to complete bony ankylosis between vertebral bodies; a previous history of trauma; single lesions; nonunion of fractures of the posterior column; acute kyphoscoliotic deformity with the lesion at the apex; instability, and the need for operative treatment due to that instability.

It is essential to distinguish between inflammatory and traumatic Andersson lesions, as the former respond to medical treatment whereas the latter require surgery.
Results
Andersson lesions were detected in 100 spinal segments in 33 patients (5.3%).

Radiological findings. Characteristics of inflammatory lesions. Inflammatory lesions were identified in 91 segments of 24 patients (3.9%) (Table I). Single lesions were seen in four patients and multiple lesions in the remaining 20. The inflammatory lesions originated in the vertebral column in the presence of incomplete bony ankylosis, and were not accompanied by instability at the apex of the lesion, or by fracture of the posterior column.

The MRI signal intensity in the adjacent vertebral bodies varied according to the duration of the inflammation. In cases of acute inflammation, low signal intensity was seen on the T₁-weighted MR images and high signal intensity on the T₂-weighted images (Fig. 2a). In the chronic phase, the situation was reversed (Fig. 2b). The mean mSASSS in these 24 patients was 16.05 (10 to 25).

Characteristics of traumatic lesions. Traumatic lesions were found in nine segments of nine patients (1.4%) (Table II) and in each case they were restricted to a single level. The ankylosed spine was severely disrupted by the lesion and there was an associated mean acute kyphotic deformity of 26.8° (12° to 39.5°) and a mean acute scoliosis of 9.3° (4° to 15°), the lesions being at the apex of the curve (Fig. 3). On MRI, lesions with low signal intensity were seen on the T₁-weighted images and lesions with irregular signals on the
T₂-weighted images (Fig. 4). Traumatic lesions occurred when bony ankylosis was relatively well developed compared to the inflammatory lesions. The mean mSASSS in these nine patients with traumatic lesions was higher than that in the patients with inflammatory lesions (34.14 (12 to 66) versus 16.05 (10 to 25), respectively).

Clinical findings. There was a difference in the mean duration of disease for the two types of lesion: 9.4 years (1.4 to 21) for the inflammatory lesions and 17.2 years (4.3 to 34) for traumatic lesions. Of the 33 patients with Andersson lesions, 11 (seven with an inflammatory lesion and four with a traumatic lesion) complained of pain at the site. However, the nature of the pain was mechanical (i.e., related to movement) in the case of traumatic lesions and inflammatory (i.e., constant pain disturbing sleep, stiffness after periods of immobility) in the case of inflammatory lesions.

A previous history of trauma was confirmed as the cause of the lesion in four of the nine patients with a traumatic lesion. All the injuries were minor (three were falls and one a traffic accident) and had occurred at a mean of 51 months (3 to 84) previously. None of the patients had any neurological abnormality.

Findings of blood and histology. The mean ESR and CRP were 42.84 mm/hr (10 to 146) and 3.09 mg/l (0.13 to 12.10) in the inflammatory lesions, respectively, and 36.79 mm/hr (4 to 76) and 2.93 mg/l (0.47 to 12.50) in the traumatic lesions, respectively. Human leucocyte antigen (HLA) B-27 was present in 21 of the 24 patients with an inflammatory lesion and in eight of the nine patients with a traumatic lesion. Biopsies were obtained from five of the patients with a traumatic lesion during the course of anterior interbody fusion. The biopsy material showed evidence of bony fragments, fibrosis and chondrodysplasia in addition to chronic inflammation.

Treatment and changes during follow-up. Patients were initially treated with non-steroidal anti-inflammatory drugs (NSAIDs). If their symptoms failed to improve, we used an anti-tumour necrosis factor (TNF) agent, especially for those with inflammatory lesions. This had an excellent effect on their back pain. In patients with an inflammatory lesion, the inflammation was suppressed and central bony ankylosis had occurred at mid- to long-term follow-up (Fig. 5a). In some cases peripheral bony ankylosis occurred around the annulus fibrosus, giving the appearance of a bamboo spine (Fig. 5b). Unlike those with inflammatory lesions, patients with traumatic lesions showed signs of spinal instability because of severe damage to the vertebral bodies and an ununited posterior column. These appearances improved with conservative treatment in three patients (Fig. 6) and after corrective surgery in five of the other six.

For these, we carried out an anterior interbody fusion around the lesion, a Smith-Petersen osteotomy in an asymmetric V-shape at the level of the lesion, and a pedicle subtraction osteotomy of the lumbar spine to correct the sagittal imbalance (Fig. 7). We achieved a mean correction of the kyphotic deformity of 8.9° (8° to 10°) and a mean correction of the sciotic deformity of 8.4° (4° to 14°). The thoracic kyphosis was corrected from a mean of 49.1° (30° to 69°) to 42.3° (25° to 57°), and the mean lumbar lordosis was corrected from -8.8° (-12° to -5°) to -39.0° (-51° to -32°). The list (the distance between a perpendicular line drawn from the centre of the C7 body to the postero-superior corner of S1) was also reduced from a mean of 8.6 cm (2.2 to 15.4) to a mean of 3.8 cm (0 to 6.5).

Discussion

The prevalence of destructive discovertebral lesions in ankylosing spondylitis ranges from 1 to 28 per 100 cases. In this study, the overall prevalence of Andersson lesions was 5.3% (3.9% inflammatory and 1.4% traumatic). The sensitivity of MRI for inflammatory lesions is known to be higher than that of plain radiography. Since only 6.3% of our patients were investigated by MRI, the real prevalence was almost certainly higher.

Infection, inflammation and pseudarthrosis have all been considered to be causes of Andersson lesions. The associated pain and radiological features are reported to have improved after treatment with NSAIDs and anti-TNF agents. However, there have also been reports that surgical intervention, in the form of interbody fusion, is needed to relieve the pain caused by instability, kyphotic deformities and neurological disorders.

In early studies the lesions were thought to be caused by infection because of their radiological similarity to an infective spondylodiscitis, but bacteriological and other investigations failed to support this view. Today, the lesions are explained in terms of inflammatory and traumatic causes. Support for an inflammatory cause is based on the absence of a previous history of trauma, features of chronic inflammation.
non-bacterial inflammation on pathological examination, and improvement of the patient’s pain and radiological features with anti-inflammatory drugs. A traumatic cause is predicated on the appearance of a nonunion after an acute traumatic or insufficiency fracture, and occurs frequently among those with a previous history of trauma and/or a heavy job, and is confirmed histologically by the presence of fibrosis and chondrodysplasia.

In this study, four of the nine patients with a traumatic lesion had a previous history of trauma, which was assumed to be the cause of the lesions, whereas patients with inflammatory lesions had no such history. Also, in five patients with traumatic lesions bony fragments, fibrosis and chondrodysplasia were found in the tissue removed during anterior interbody fusion.

Narrowing of the disc space and abnormal radiodensity of the vertebral body have been reported as being characteristic features of inflammatory lesions, and this was confirmed by our study. Many of the features of inflammatory lesions are similar to those of Romanus lesions, which are early inflammatory lesions located in the anterior corners of the vertebral bodies; apart from the difference in location, they are radiologically identical and, in particular, give the same changes in signal intensity on MRI. By contrast, widespread destruction of the vertebral body and discs, and nonunion of the resultant posterior column fractures, have been reported as distinctive features of traumatic lesions. These characteristics were also confirmed by this study.

Owing to the inflammatory nature of the disease more than half of all patients with ankylosing spondylitis develop osteoporosis. Because of this and the reduced spinal flexibility due to bony ankylosis, these patients are thought to be more susceptible to spinal fractures. This view was confirmed in this study, as patients with a traumatic lesion had a higher mSASSS than those with

Figure 5a – radiograph (left) and T₂-weighted MR scan (right) showing central (transdiscal) bony ankylosis at the levels T12-L1 and L2-3 in a case of inflammatory Andersson lesion. Figure 5b – radiograph (left), CT scan (centre) and T₂-weighted MR scan (right) showing peripheral (prediscal) bony ankylosis at the whole lumbar spine.
inflammatory lesions. It is also reported that the stresses around the thoracolumbar junction are radically increased when these lesions are accompanied by a kyphotic deformity. Among the nine cases of traumatic lesions in this study, increased stress was generated at the thoracolumbar junction in six cases, between T10 and T11 in two further cases, and between L1 and L2 in the remaining case. Once a fracture occurs in an ankylosed spine, bony union is hampered by constant movement at the solitary mobile segment between two long fused segments. Consequently, traumatic lesions tend to have radiological features that differ from those of inflammatory lesions, and resemble hypertrophic pseudarthrosis-like nonunions in a long bone with nonunion and delayed union of the associated posterior column fracture. This was true of all nine patients in our study.

Pain and the evolution of deformity due to instability have previously been reported. In this study, three of the four patients with a traumatic lesion who complained of pain were found to have a radiologically unstable spine.

In summary, in this study we subdivided the discovertebral (Andersson) lesions of ankylosing spondylitis into inflammatory and traumatic types and confirmed the clinical and radiological differences between the two. The fact that many previous studies used a single term for two quite different pathological phenomena has caused a great deal of confusion. We believe our findings permit a clear distinction to be made between the two types. This should
clarify the clinical picture and provide the appropriate criteria for determining treatment. Put simply, we suggest that anti-TNF agents be used to treat the pain of inflammatory lesions, whereas operative treatment be used to alleviate the pain, deformity and instability of traumatic lesions.
