ONCOLOGY

Clinical outcome and quality of life after surgery for peri-acetabular metastases

We set out to determine the impact of surgery on quality of life and function in patients who had undergone surgery for symptomatic peri-acetabular metastases. From a prospective database we retrospectively reviewed 46 consecutive patients who had been treated operatively between June 2003 and June 2009. The mean age of the patients was 56.4 years (20 to 73) and the mean post-operative follow-up was 19.2 months (4 to 70). Functional evaluation and quality-of-life assessments were performed. At the most recent follow-up, 26 patients (56.5%) were alive. Their median survival time was 25.0 months. Ten major post-operative complications had occurred in eight patients (17.4%). The mean post-operative Musculoskeletal Tumor Society score (MSTS 93) was 56.3% (6.7% to 90.0%). Improvement in the Eastern Cooperative Oncology Group (ECOG) performance status was seen in 32 patients (69.6%). On the European Organisation for Research and Treatment of Cancer core quality-of-life questionnaire (QLQ-C30) measure of global health status there was a statistically significant improvement from the patients’ pre-operative status (42.8 (SD 13.7)) to that found at the latest follow-up (58.0 (SD 12.5)) (p = 0.001). The only statistically significant change in the nine symptom domains of the QLQ-C30 was a reduction in the mean level of pain (from 59.1 to 29.5 (out of 100)) (p < 0.001).

Surgery for patients with peri-acetabular metastases reduces pain and improves their quality of life, and has a low rate of surgical complications.

Improvements in the treatment of cancer have resulted in prolonged survival and an increase in the number of patients with metastases.1 Metastatic bone disease affecting the pelvis and acetabulum is increasingly encountered by oncologists and orthopaedic surgeons.2-4 Some metastatic deposits are associated with instability of the acetabulum, which may cause severe pain and functional disability. An effective method of treatment should relieve pain and restore function for as long as possible.5

It has been shown that surgery can reduce the morbidity of metastatic bone disease, relieve pain, maintain mobility and independence and improve the patient’s quality of life.5-8 Surgical reconstruction of peri-acetabular pelvic lesions is complex, involving long operating times, extensive exposure and considerable blood loss.9-11 The effect of this surgery on quality of life (QoL) remains unknown.12 Most studies have dealt with surgical procedures and survival; few have addressed the QoL of patients after surgical treatment for peri-acetabular metastases.6 We believe that a multidimensional assessment of QoL is more relevant to the management of these patients, particularly when assessing the risks and benefits of surgery.

The purpose of this study was to determine the impact of surgery on health-related QoL and function in survivors after surgical treatment for peri-acetabular metastases.

Patients and Methods

From a prospective database we retrospectively reviewed 46 consecutive patients treated operatively for symptomatic metastatic peri-acetabular disease between June 2003 and June 2009. Exclusion criteria included previous surgery for pelvic metastases and an inability to complete a questionnaire. The medical records and radiographs of these patients were reviewed after approval by the Institutional Review Board. Informed consent for participation in the study was obtained from the patients or their families. The local extent of the tumour, type of excision and reconstruction performed were noted. The patients were assessed before surgery and at three and six months after surgery. Findings at the most recent review were recorded for the patients who were still alive. Their survival
was calculated from the date of surgery to death, or to the
date of the last follow-up. The indications for surgery were
intractable pain unresponsive to conservative treatment,
significant interference with mobility, a slow to moderately
growing tumour, and a primary tumour that was stable
after chemotherapy and/or radiotherapy.

Imaging of the symptomatic region with plain radio-
graphs and cross-sectional studies (MRI or CT) was
undertaken in all patients to assess the intra- and extra-
ossous extent of the tumour. A whole-body bone scan was
also routinely performed. Complete evaluation of the
ipsilateral bone was carried out so that synchronous meta-
stases could be treated appropriately. Percutaneous core-
needle biopsy was performed on patients with an unknown
primary tumour. Internal iliac vessel embolisation was per-
fomed in six patients on the day before their operation.

Ipsilateral internal iliac artery ligation and temporary
occlusion of the abdominal aorta with nylon tape or an
intra-aortic balloon catheter were used in selected cases of
tumours with excessive blood supply, those tumours with a
diameter of > 10 cm, and those with involvement of the
sacroiliac joint, in order to minimise intra-operative blood
loss. Thus the internal iliac artery was ligated in
14 patients, eight of whom also had temporary occlusion of
the abdominal aorta using a nylon tape. An intra-aortic
balloon catheter was used in eight patients.

Resection of the tumour was carried out using different
surgical approaches depending on the extent and location
of the individual tumour. According to Harrington’s classi-
fication, patients with a class I defect were treated by rou-
tine hip replacement and cement augmentation on the
acetabular side through a lateral transgluteal approach. For
other types of defect, a T-shaped incision consisting of some
or all of an extended ilioinguinal incision combined with a
Smith-Petersen approach was used. Gross tumour and
bone fragments were removed until solid bone could be
palpated. For class II defects, a type of antiprotrusio tita-
nium acetabular mesh (Link, Hamburg, Germany), with a
small peripheral lip which sits on the lateral cortex of the
ilium above the acetabulum, was placed over the deficient
medial wall to prevent extravasation of cement into the pel-
vis. Additional fixation screws were placed through the
dome before cementing in a polyethylene cup, which varied
according to the prostheses being employed (Fig. 1). An
Endo-Model Partial Pelvis Replacement (Link, Hamburg,
Germany) was used for class III defects treated by curet-
tage. These devices include a groove for implantation of a
cemented acetabular component, and two or three fixation
arms for screw fixation to the surrounding pelvic rim
(Fig. 2). After resection of the femur a conventional
cemented femoral component was used. If the tumour
involved the proximal femur, it was replaced by a femoral
endoprosthesis. For class IV defects, a modular hemipelvic
endoprosthesis (Chunli, Beijing, China) was used after en
bloc resection of the tumour (Fig. 3). The femoral side was
then reconstructed using a standard component.

Quality of life was assessed using the European Organi-
sation for Research and Treatment of Cancer core quality-
of-life questionnaire (EORTC QLQ-C30). This has nine
multi-item scales: five functional scales (physical, role,
emotional, social and cognitive function), three symptom
scales (pain, fatigue and financial difficulties), and a global
health and quality-of-life scale. Each health profile is scored
on a 100-point scale: a higher score in the functional scale
indicates less disability, whereas a higher score in the symp-
tom scales reflects a heavier symptomatic burden. A higher
score on the global health and quality-of-life scale indicates
better health and better quality of life. The Eastern
Cooperative Oncology Group (ECOG) performance status
grades were also collected. This measures functional per-
formance on a scale from 0 to 4, where 0 represents normal
activity and 4 signifies totally bedridden. Function related
to surgical treatment was assessed using the Musculoskeletal Tumor Society (MSTS 93) system developed by Enneking and Dunham.\textsuperscript{18}

**Statistical analysis.** Statistical analysis was carried out using SPSS software package version 16.0 (SPSS Inc., Chicago, Illinois). The Kaplan-Meier approach was used to estimate survival probabilities and median survival times. The log-rank test was used to compare the survival of subgroups. Paired $t$-tests were used to assess the significance of the difference between the pre-operative and most recent scores. A $p$-value $< 0.05$ was chosen to represent significance. Because the QLQ-C30 was a multidimensional method of assessment, each domain was analysed and presented separately.

**Results**

There were 28 women and 18 men, with a mean age of at the time of surgery of 56.4 (20 to 73). The mean time from the diagnosis of the primary cancer to the manifestation of the acetabular lesion was 21.6 months (2 to 23). The mean follow-up was 19.2 months (4 to 70). A total of 19 patients (41.3%) had multiple bone metastases and 11 (23.9%) had visceral metastases. Table I summarises the extent of disease by site of the primary tumour, and the details of the surgery are summarised in Table II.

Results of surgical treatment. The mean blood loss was 2464.1 ml (300 to 10 500) and the mean operative time was 3.6 hours (2 to 6). There were no peri-operative deaths. Adjuvant treatment was used in 37 (80.4%) patients: systemic chemotherapy in 16 cases, radiotherapy in nine and combination therapy in 12.

There were ten major post-operative complications in eight patients (17.4%), including six cases of local progression of disease, two cases of deep infection and two cases of dislocation. Four of these eight patients received chemotherapy for their primary tumour. The mean time to local progression of disease was 7.5 months (3 to 12). Two deep infections were successfully treated with debridement. Six patients with local recurrence had a further tumour resection; one with renal cell carcinoma survived. Hip dislocations were treated by revision.

A total of 26 patients (56.5%) were alive at follow-up and 20 patients died of primary tumour progression at between 4 and 36 months after the peri-acetabular operation. The Kaplan-Meier curve for overall survival is shown in Figure 4. The median survival of the 46 patients was 25 months; of the survivors at final follow-up, 17 were with disease and nine were disease-free. All those with myeloma and carcinoma of the prostate survived. The ten patients with renal cell carcinoma had a median survival of 36.0 months (interquartile range (IQR) 25 to n/a), patients with breast carcinoma 16.0 months (IQR 16 to n/a), lung cancer 14.0 months (IQR 10 to 19), and hepatic carcinoma 11.0 months (IQR 10 to n/a). The cause of death in each case was progression of the disease. The mean period of survival of patients with visceral metastases was 17.0 months (95% CI 10.4 to 23.6), whereas that of patients without visceral metastases was 42.1 months (95% CI 30.7 to 53.4) (p = 0.01). Patients with multiple skeletal metastases had a shorter mean survival (29.8 months, 95% CI 18.2 to 41.5) than patients with a solitary metastasis (32.6 months, 95% CI 22.7 to 42.5), although no significant difference was found (p = 0.50).

Post-operative function. The mean MSTS 93 score was 56.3% (6.7% to 90.0%) for all 46 patients at latest follow-up. Of each patient’s last follow-up, a total of ten of the 46 patients needed medication for constant pain, one of whom had severe pain requiring the continuous use of narcotics. Nine had moderate pain requiring the periodic use
of narcotics, and five had mild pain requiring the use of non-narcotic analgesics. The mean rating out of 5 for emotional acceptance was 2.5 (0 to 5). In all, 25 patients (54%) required at least the occasional use of a stick or one crutch at their last follow-up, and 21 patients could walk without support. The mean score for support was 2.8 out of 5. The total of 26 surviving patients were found to have been relieved of pain at a mean follow-up of 19.2 months.

Discussion

The treatment of metastatic disease of the acetabulum is a fine balance between survival, function and overall QoL. Because of the patient’s limited life expectancy, function and QoL are profoundly important considerations. If their symptoms can be controlled and a satisfactory level of function achieved, they may be able to return home and have some social life. Understanding how they function after surgery is the first step in optimising their treatment. An understanding of the relationship between pain, function and QoL will help the surgeon decide when to consider reconstructive surgery.

There is no doubt that in appropriately selected patients, surgical treatment can improve various aspects of quality of life, such as pain and mobility. However, the effect of this surgery on their overall quality of life has not previously been discussed. Published studies using validated outcomes tools to assess QoL after surgical treatment of bony metastases are rare. Furthermore, surgery for pelvic metastases is associated with significant morbidity, which may adversely affect other aspects of quality of life. Currently, there are no specific guidelines as to when to intervene surgically. This depends on the patient’s wishes, the surgeon’s experience, the perceived efficacy of medication and radiation, and nutritional and haematological parameters, and is necessarily tailored to the individual. Our results have shown that surgical intervention reduces pain and improves the overall QoL in patients with acetabular metastases who undergo reconstructive surgery.

Marco et al reviewed 55 patients who underwent pelvic reconstruction and suggested modifying the Harrington system of evaluating metastatic disease of the acetabulum.

</table>
The two-year survival in our series was 51.5% which is similar to the 52% reported by Harrington. Vena et al described the outcome of 21 patients with peri-acetabular metastases. Their mean post-operative survival was 14.5 months. The nature of the primary tumour and the degree of its systemic progression are important determinants of life expectancy. Althausen et al reported that long-term disease-free intervals can be achieved in patients who have undergone resection of a primary tumour of the kidney with an isolated metastasis in bone. More than half the patients in our study had a primary tumour of slow to moderate growth, such as cancer of the breast, thyroid or kidney. Six of the nine patients who died within a year of surgery for peri-acetabular metastases had cancer of the lung or liver. Local recurrence occurred in six patients in our study. Three of the six cases were reconstructed with an antiprotrusio mesh, and two had partial replacement of the pelvis. The relatively low recurrence rate in this group of patients may be attributed to en bloc resection and more aggressive local and systemic treatment. Yasko et al reported no local recurrence after en bloc resection for peri-acetabular metastases in 14 consecutive patients. In our series, this was carried out in 14 (30.4%) patients and aggressive adjuvant treatment was used in 37 (80.4%). The four patients who had a recurrence were all treated by curettage, and three of these received no adjuvant treatment. The comparatively low complication rate was attributed to a highly trained, multi-surgeon team, operating expeditiously, and to effective intra-operative control of haemorrhage.

Harrington's classification is generally used to describe the extent of metastatic disease of the acetabulum. According to this classification, patients with a class I defect can be treated by routine hip replacement with cement augmentation of the acetabular and femoral side. A titanium mesh is often incorporated to support the medial wall and to prevent migration of the cement and acetabular component into the pelvis. A variety of antiprotrusio acetabular devices have been developed to reinforce the margins of the acetabulum, which may make reconstruction easier. No threaded pins, inserted either antegrade or retrograde, were used for reinforcement in this study. For some type II defects, the Endo-Model partial pelvic replacement was used instead of threaded pins. En bloc resection may be more appropriate when advanced disease precludes internal fixation, or when the metastatic disease is limited to a solitary bony deposit. Falkinstein, Ahlmann and Menedez reported 13 patients with peri-acetabular metastases who underwent en bloc resection and prosthetic reconstruction. Of the 14 patients in our series who underwent en bloc resection, 12 had a solitary bony metastasis. Six of these 14 patients had metastases from a renal cell carcinoma.

Reconstruction after en bloc resection inherently increases the complexity of surgery. Satisfactory results have been reported following the use of the modular hemipelvic endoprosthesis. In our series, most of the metastases were large, with extrapelvic soft-tissue extension. Eight of the patients had involvement of the ilium and/or obturator pubic and ischium. In one patient with breast cancer the whole hemipelvis was involved. One (8.3%) local recurrence was seen three months post-operatively. The complication rate for the 14 patients who underwent en bloc resection was 14.3%, higher than that for those who had undergone curettage (6.3%). No survival benefit was found from en bloc resection compared with curettage (p = 0.61). En bloc spondylectomy for spinal metastases has been developed in recent years. The value of en bloc resection for peri-acetabular metastases remains undetermined.

The mean post-operative MSTS 93 score was compared with others in the literature. Vena et al described the outcome of 21 patients with a mean MSTS 93 score of 47.3%. Ho et al reported a mean post-operative MSTS 93 score of 67% in 37 patients with peri-acetabular metastases. However, the MSTS 93 scores in our cohort were lower than those following the treatment of primary malignancies of the peri-acetabular region. This may be because of the general condition of the patients, most of whom received chemo- and/or radiotherapy for primary cancer, and systemic progression of the metastatic disease. The physical activity level of the patients was improved significantly according to their ECOG scores. A total of 17 (37.0%) patients performed well (an ECOG status of 0 or 1) post-operatively, compared with three (6.5%) pre-operatively.

A number of instruments have been used to assess global quality of life in patients with cancer. Most of these have been designed either for the general population or for patients who are undergoing potentially curative treatment for cancer. It is important to note that palliative care patients differ from these groups. The QLQ-C30 is a validated instrument used for the study of health-related quality of life in cancer patients. The QLQ-C30 assessment showed a statistically significant improvement after surgery for overall health status. We found significant changes only for global QoL and pain. This confirms the central importance of pain in a patient’s overall assessment of quality of life. Some studies have found a statistically significant correlation between QoL and survival time. It is reasonable to expect that an improvement in the control of pain would result in an improvement in QoL. As pain becomes more severe, it will have a greater effect on function. The post-operative QLQ-C30 scores were close to those reported by Hoffmann et al after the treatment of patients with primary malignancy of the pelvis.

This study has limitations, the main one being an inability to analyse how function and QoL change with time. The best way to evaluate post-operative function is by dynamic analysis and follow-up at different intervals after surgery. Owing to well-recognised difficulties in clinical follow-up, insufficient data were collected for analysis. However, the overall influence of surgery on outcome at a certain time point was still helpful when considering surgical
intervention. There was no control group, for which it is unlikely that ethical approval would have been granted. The instruments used have all been validated in previous studies, but their limitations also need to be noted. Only half the patients survived, so the complication rate may not be accurate. A longer period of follow-up may reveal a higher complication rate. Despite these limitations, this study clearly shows that, in patients who have metastatic involvement of the acetabulum, surgical intervention offers benefits in terms of pain relief and improved QoL, with an acceptable rate of complications.

No benefits in any form have been received or will be received from a commercial party related directly or indirectly to the subject of this article.
